Abstract: This study investigates the seismic performance enhancement of Reinforced Cement Concrete (RCC) buildings using passive energy dissipation systems, specifically friction dampers and shear walls. In earthquake-prone regions, RCC structures are vulnerable to seismic damage, necessitating the incorporation of advanced structural design features. The research involves modelling two types of G+14 high-rise RCC buildings a regular-shaped and a Plus-shaped configuration using ETABS software, and analysing them under Seismic Zone V conditions per IS 1893:2016 Part 1. Various support systems, including bare frames, friction dampers, and shear walls, were assessed based on key parameters such as storey displacement, storey drift, storey shear, overturning moment, and base shear. The results reveal that the Plus-shaped building with shear walls (Structure VI) exhibits the most effective seismic resistance, showing the lowest storey displacement (14.47 mm) and minimum story drift. Additionally, the highest base shear (2606.01kN) was observed in this structure, indicating enhanced energy dissipation. Comparatively, the Plus-shaped structure with friction dampers (Structure V) demonstrated the highest storey shear, highlighting the dampers' role in lateral force management. While overturning moments increased marginally, they remained within safe limits. This comprehensive analysis emphasizes the critical role of friction dampers and shear walls in improving seismic resilience. The findings support the strategic integration of these systems, particularly in irregular structures, to enhance overall stability and safety during seismic events.

Keywords: Friction Dampers, Seismic Performance, RCC Structures, Shear Walls, ETABS Analysis

1. Introduction

Earthquakes pose a significant threat to structures, particularly in seismically active regions. While reinforced concrete (RCC) buildings are widely used for their strength and versatility, they remain susceptible to damage during seismic events. To enhance their seismic resistance, modern design practices have adopted passive energy dissipation devices, such as friction dampers, which play a vital role in minimizing structural damage by reducing vibrations during earthquakes.

Friction dampers function by converting seismic energy into heat through controlled sliding between two surfaces under pressure. This energy dissipation mechanism reduces the amplitude of seismic-induced vibrations, thereby protecting the building from excessive stress and potential collapse. This study investigates the performance of friction dampers in improving the seismic behaviour of RCC structures, alongside shear walls, which are another common seismic resistance element.

The research involves the modelling and seismic analysis of two RCC structures -one with a regular G+14 layout and the -other with a Plus-shaped layout using ETABS software. Both structures are assessed with different support systems: friction dampers and shear walls, under Zone V seismic conditions as per IS 1893:2016 Part 1. The analysis focuses on critical structural parameters such as story displacement, story drift, story shear, overturning moment, and base shear.

Seismic design requires a deep understanding of dynamic loads, material behaviour, and structural configuration. Common mitigation techniques include base isolation, energy dissipation devices (viscous dampers, yielding steel braces, and friction dampers), and seismic retrofitting. Among these, dampers are especially effective in reducing structural vibrations during seismic motion. IS 1893:2016 provides the guidelines for calculating seismic loads and ductility design to ensure structural safety.

ETABS, a widely used software for seismic analysis, enables accurate modelling of RCC structures by incorporating material properties, dimensions, and reinforcement data. It ensures code compliance and helps simulate realistic behaviour under various loading conditions.

2. Objectives of the Study

- To evaluate the effectiveness of friction dampers in improving the seismic performance of RCC buildings in Seismic Zone V.
- To assess the role of shear walls in enhancing seismic resistance.
- To compare the seismic response of a regular-shaped structure and a Plus-shaped structure.
- To analyse key parameters including story displacement, story drift, story shear, overturning moment, and base shear.
- To investigate the optimal placement and sizing of friction dampers for maximizing structural stability during earthquakes.

3. Methodology

3.1 General

The design process for all the structural instances is presented in this section. This thesis conducts a thorough analysis and comparison of the seismic performance of reinforced cement concrete (RCC) structures with and

without friction dampers and shear walls. The study focuses on buildings located in Seismic Zone V, which has a zone factor of 0.36, and on soil type III (soft soil), which is particularly susceptible to seismic pressures. Friction dampers, a kind of passive energy dissipation device, enhance structural performance by reducing lateral vibrations by distributing seismic energy through regulated frictional resistance.

3.1 Steps involved in methodology and design process

Step 1: Initialization of the structure which is focused towards analyzing multi-story high-rise structures considering seismic loads with same seismic zones and soil condition.

Step 2: In order to initiate the modelling of the case study, firstly there is a need to initialize the structural model on the basis of defining display units on metric SI in region India as ETABS supports the building codes of different nations. The steel code was considered as per IS 800:2007 and concrete design code as per IS 456:2000.

Step 3: ETABS provides the option of modelling the structure with an easy option of Quick Template where the grids can be defined in X, Y and Z direction. Here in this case, we are considering 45m long Regular and Plus Shaped Building. G+14 story structure is considered with typical story height of 3 m and Bottom story height of 3 m.

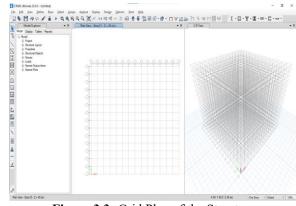

Figure 3.3: Grid Plan of the Structure

Step 4: Next step is to define the material properties of concrete and steel. Here in this case study, M30 concrete is considered and its predefined properties are available in the ETABS application.

4. Results & Discussion

4.1 General

The observed results are shown in this section. This thesis conducts a thorough analysis and comparison of the seismic performance of reinforced cement concrete (RCC) structures with and without friction dampers and shear walls. The study focuses on buildings located in Seismic Zone V, which has a zone factor of 0.36, and on soil type III (soft soil), which is particularly susceptible to seismic pressures. Friction dampers, a kind of passive energy dissipation device, enhance structural performance by reducing lateral vibrations by distributing seismic energy through regulated frictional resistance.

 Table 4.1 Maximum story displacement in mm

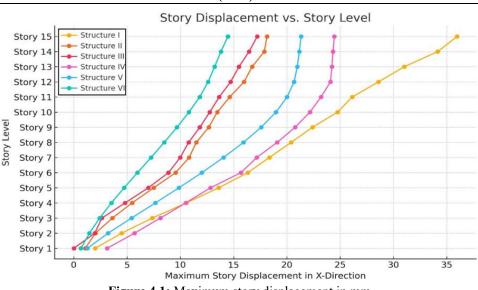

Figure 4.1: Maximum story displacement in mm

Inference- The different structure shapes were compared with bare frame supported with friction dampers and shear wall and similar results were compared for the plus shape structure with friction dampers and shear walls at the corners. The story displacement was found to be stable in all the compared cases but the least maximum displacement was visible for Structure VI as 14.47 mm which was 49.21 % less than Structure IV and 61.19% less when compared to bare frame Structure I.

DOI: https://dx.doi.org/10.70729/SE25519112125

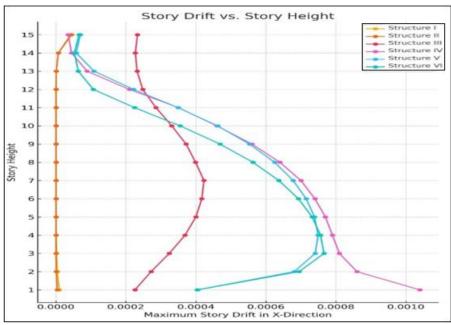

Figure 4.2: Story Drift

Inference- According to the investigation, it was found that the story drift of Plus shaped Structure IV was minimum and the frame is much stiffer than the others. Story drift depends upon the relative displacement to its height. Structure IV shows the highest story drift in most cases, meaning it experiences the most significant relative displacement. This suggests that its design is less effective in controlling lateral movements compared to the other structures. There are a number of possible explanations for this discrepancy, including differences in the other Structures loading circumstances, material composition, or structural design.

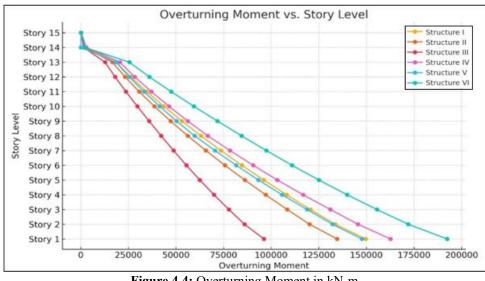

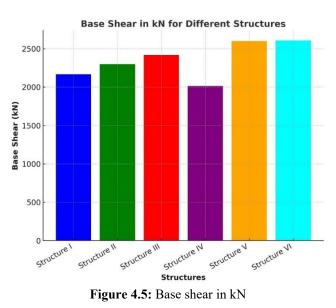

Figure 4.4: Overturning Moment in kN-m

Inference: The Overturning moment is the sum of all forces that can cause a structure to tip over around a pivot point, typically at or near its foundation. It's a measure of the potential for a structure to become unstable and turn over. The maximum story overturning moment of Structure VI was 9.8% more than that of Structure I. This suggests that the Structure VI experiences slightly higher rotational force due to slightly higher lateral forces than the other compared Structure. However, the overall overturning moment of the two Structure does not differ significantly.

4.6 Base shear in X-direction

Fable	4.5:	Base	shear

		Base Sh	ear in KN		
Structure I	Structure II	Structure III	Structure IV	Structure V	Structure VI
2167.513	2298.308	2418.281	2012.908	2598.655	2606.011

Inference: Base shear is used in the design of buildings to ensure they can withstand seismic activity. It is the maximum lateral force that acts on the base of a structure during an earthquake. It's a key property of a structure that's calculated during structural analysis. The base shear of Structure VI was 37.1% greater than that of Structure I. This might be explained by differences in the two structure loading circumstances, material composition, or structural design.

5. Conclusion

This study compared the seismic performance of RCC buildings with two structural configurations Regular and Plus-shaped under various support systems, including shear walls and friction dampers. Key seismic parameters such as story displacement, story drift, story shear, overturning moment, and base shear were analysed. The results indicate that Structure VI (Plus-shaped with shear walls) demonstrated the best overall performance, showing the lowest storey displacement (14.47 mm), which was significantly lower than both the bare frame and other configurations. It also exhibited the minimum storey drift, reflecting better control over lateral movements. In terms of storey shear, Structure V (Plus-shaped with dampers) experienced the highest lateral force, suggesting increased energy dissipation. For the overturning moment, Structure VI showed only a moderate increase (9.8%) compared to the bare frame, indicating slightly higher rotational forces but within safe limits. Finally, base shear was highest in Structure VI about 37.1% more than the bare frame implying greater resistance to seismic forces due to improved structural configuration and support. Overall, the integration of shear walls and friction dampers, particularly in a Plus-shaped structure, significantly enhances the seismic performance of RCC buildings.
